DISCLAIMER

This report has been reviewed by the Office of Radiation Programs - Las Vegas Facility, U. S. Environmental Protection Agency, and approved for publication. Mention of trade names or commercial products does not constitute endorsement or recommendation for their use.

PREFACE

The Office of Radiation Programs of the U.S. Environmental Protection Agency carries out a national program designed to evaluate population exposure to ionizing and nonionizing radiation, and to promote development of controls necessary to protect the public health and safety. This report describes several field studies which were conducted to evaluate the ambient airborne radioactivity levels for locations in the vicinity of the Jackpile Open Pit Uranium Mine in New Mexico. Readers of this report are encouraged to inform the Office of Radiation Programs of any omissions or errors. Comments or requests for further information are also invited.

The authors would like to extend their grateful appreciation to The Anaconda Company and Mr. William E. Gray for their cooperation during this study.

INTRODUCTION

Starting in December 1975, a one-year study was conducted in the vicinity of the Jackpile Open Pit Uranium Mine to measure the ambient airborne concentrations of natural radioactive materials such as uranium, radium and thorium. Radon progeny levels (expressed as Working Levels [WL]) were also determined at several indoor locations in nearby communities. During June 1976, a special study was conducted to measure the ambient outdoor radon-222 levels in the area. This report discusses the results of these radiological surveys.

SUMMARY

This report discusses the results of several radiological surveys conducted in the vicinity of the Jackpile Open Pit Uranium Mine in New Mexico. During June 1976, ambient radon-222 concentrations were measured at eleven locations, seven of which appear to have been at representative background radon levels - averaging 0.50 ± 0.033 pCi/l. The other four locations had average radon levels in excess of this typical background level; however, the highest measured radon concentration was 2.7 pCi/l. The arithmetic average ambient radon progeny working level obtained indoors at the Laguna Tribal Building appeared to be at a representative background level of 0.0049 ± 0.00045 WL. The arithmetic average ambient working levels obtained at the Paguate Community Center and the Jackpile Housing were 0.035 ± 0.0038 and 0.015 ± 0.0025 WL, respectively. Ambient airborne particulate radioactivity concentrations measured outdoors at Old Laguna appear to be at typical background levels; however, other locations exhibited higher annual average concentrations for the naturally-occurring radionuclides.

STUDY AREA

Figure 1 shows the study area and sampling locations. The Anaconda Company operates the Jackpile-Paguate Mine which is the world's largest open pit uranium mine. About 5500 tons of uranium ore are produced each day. Roughly one-half of the daily production is sent via railway for processing at the Anaconda Mill at Bluewater; the remaining ore is stockpiled at the mine.

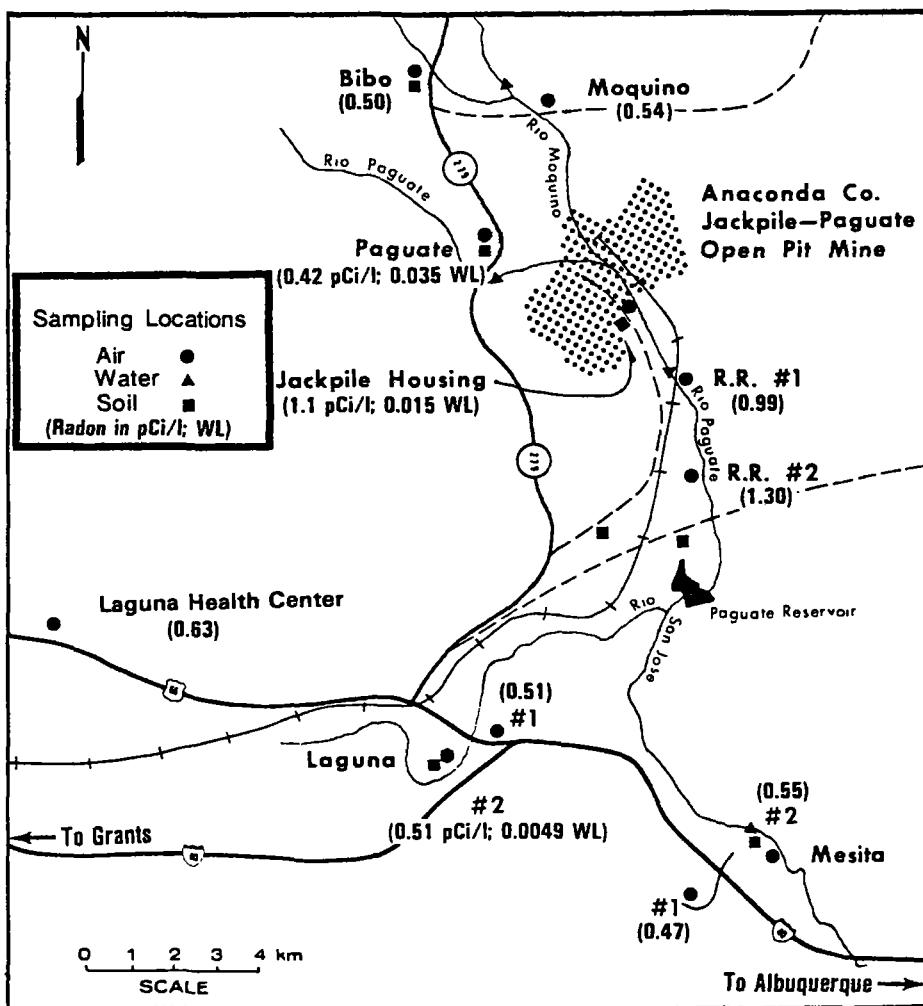

Figure 1. Sampling locations and summary of radon and progeny measurements in the vicinity of the Jackpile Open Pit Mine, New Mexico

RADIATION SURVEYS

Upon selection of a site as a suitable air sampling location, gamma radiation surveys were completed. These surveys were done to evaluate whether the sampling location was constructed upon an area of elevated terrestrial radioactivity, or if some uranium ore or other radioactive material was present inside the structure. Such conditions could have biased the ambient outdoor radon levels and/or the indoor working level determinations.

A pressurized ionization chamber (PIC - Reuter Stokes, Model RSS-111 Environmental Radiation Monitor) was used to measure the radiation exposure rate in units of microroentgen per hour ($\mu\text{R}/\text{h}$). The PIC was calibrated using a "shadow shield" method employing a cobalt-60 source calibrated by the National Bureau of Standards. The PIC was then inter-calibrated to respond to a radium-226 gamma spectrum. The PIC measures both the cosmic and terrestrial gamma source exposure rates. All PIC measurements were made at a height of one meter above ground surface. For the indoor measurements, the PIC determination was made in about the center of the room in which the indoor radon progeny air sampler was located.

Radiation surveys were also made using a portable gamma scintillator survey meter (Baird-Atomic, Type NE148A - Gamma Scintillator Ratemeter). This instrument was calibrated with a radium-226 standard and measured the relative gamma radiation exposure rate in units of $\mu\text{R}/\text{h}$. Table 1 presents the radiation exposure rates measured at each location (indoor and outdoor) for both types of detectors.

RADIUM IN SOIL AND WATER SAMPLES

In addition to the radiation survey, a soil sample was also collected at several of the outdoor air sampling locations. Each soil sample was obtained at the same location as were the outdoor radiation measurements. The results of analyses for radium-226 content are also reported in Table 1. A standardized sampling procedure, which utilized a steel scoop, 5-cm deep and 100-cm² in surface area, was established to obtain a standard soil sample of 500 cm³, representing the average activity in the top five centimeters of soil. The highest radium content in soil (3.9 pCi/g) was at the Jackpile Housing Area. The soil content at the Railroad Trestle was also high at 1.7 pCi/g. Both of these areas showed elevated radon levels, as discussed later. The background location at Laguna (#2) had the lowest radium in soil content of 0.62 pCi/g.

Four non-potable water samples were collected from nearby streams and these results are also shown in Table 1. Radium-226 in the total water sample (both dissolved and suspended components) was measured, ranging from a low of 0.15 pCi/l at the Rio Moquino to a high value of 4.7 pCi/l for a stream near the railroad trestle.

METEOROLOGY*

Surface winds are monitored continuously at the Jackpile-Paguate mine by the Anaconda Company using a Bendix Aerovane wind transmitter located on the roof of the maintenance shop. The approximate height of the instrument is 60 feet above ground level. Wind speed and direction are recorded on analog recorders and later reduced to hourly averages by Anaconda personnel.

Surface winds at the mine occur primarily from the east and west. The nocturnal wind (1800-0600 MST) is characterized by light, westerly flow influenced by drainage from nearby terrain. During the early morning period (0000-0600 MST) westerly flow accounts for 41.5 percent of all occurrences; 27.4 percent are less than 5 mph. During the late evening (1800-2400 MST), flow is also westerly, although wind speeds average slightly higher.

The daytime wind (0600-1800 MST) is characterized by light to moderate flow distributed primarily between the eastern and western sectors. The influence of drainage winds from the west can be seen to diminish during this time as wind speeds in these sectors increase. In the morning period (0600-1200 MST) light to moderate winds still account for the majority of occurrences although they are increasingly associated with easterly flow. By afternoon (1200-1800 MST) light winds account for only a small fraction of occurrences in either the western or eastern sectors; moderate to strong winds predominate in both.

Wind speeds at the mine exemplify the early morning effect of drainage winds, which are replaced later in the day by strong westerly flow. Wind speeds in the early morning average 5.6 mph and increase to an average of 10.6 mph during 1200-1800 MST. Although winds are more frequent from the east during this period, the stronger winds are associated with westerly flow; wind speeds in this sector average 13.5 mph between 1200-1800 MST.

* This section provided by The Anaconda Company (1976).

Wind speeds at the mine are generally of light to moderate intensity with wind speeds greater than 15 mph accounting for less than 11 percent of all occurrences. Average wind speeds range from 5.3 mph from the east to 11.6 mph from the west-northwest. The strongest winds generally occur from the WNW although the frequency of their occurrence is extremely small. Maximum hourly average wind speeds are most prevalent during the afternoon hours (1200-1800 MST); ranging from 18.0 mph from the ENE to 45 mph from the WNW.

Wind speeds and directions recorded by Anaconda at the maintenance shop provide a general indication of surface winds in the area but, because of the irregular terrain, should not be considered representative of any other specific location at the mine.

AMBIENT OUTDOOR RADON-222 CONCENTRATIONS

SAMPLING SYSTEM AND ANALYTICAL METHODS

A continuous, low-volume, 110-volt AC sampling system was used to obtain the ambient outdoor sample (U.S. Public Health Service, 1969). This sampling technique consisted of pumping filtered air via a small, low-volume air pump (less than 10 ml/min sampling rate) into a 30-liter Tedlar bag*. The air intake was about one meter above the ground surface. Usually a continuous 48-hour air sample was collected in the Tedlar bag which was then transported to the laboratory facility for radon content analysis.

Radon analyses were completed at the Eberline Instrument Corporation, in Albuquerque, New Mexico. Eberline flow thru cells (volume of 0.51 liters), similar to the radon scintillation flasks described by George (1976), were used for radon analysis. The cells were counted on the Eberline SAC R-5 counting system for a 100 minute counting period. The minimum detectable activity (MDA)** achieved for these particular cells and counting system was 0.12 pCi/l. Replicate analysis was also completed at the Environmental Monitoring and Support Laboratory in Las Vegas (EMSL), as discussed in another section.

RESULTS AND DISCUSSION

Table 2 summarizes the results of this study. Ambient radon concentrations ranged from the minimum detectable activity (MDA - also shown as less than or as < in the following tables) of 0.12 pCi/l to the highest level observed for 2.7 pCi/l. These summary results are also shown on Figure 1. Basic data for each sampling location are presented in Appendix A, Tables A-1 to A-11. The lowest average radon concentration measured (0.42 ± 0.14 pCi/l)*** was at the Paguate

* Air Sample Bag made of 0.002 inch (2 mil) thick Du Pont Tedlar (T.M.) poly vinyl fluoride (PVF) material; from Environmental Measurements, Inc., San Francisco, CA.

** MDA was defined as that sample net activity which was equal to the total counting error term (due to both sample and instrument background) at the 95 percent confidence level.

*** The error term associated with average determinations is two times the standard deviation of the sample population divided by the square root of the number of samples.

** Average Result ± Two-Standard Error Terms (i.e., standard deviation of the sample population divided by the square root of the number of samples)

Community Building (Table A-8), which is directly west and roughly within two kilometers of the border of the active open pit mining area. Six other locations appear to have average ambient radon concentrations which fluctuate within the two-standard error terms about the Paguate results. Therefore, these seven locations have been considered as representative background areas and the ambient radon levels measured at these locations are listed in Table 3. In summary, ambient radon levels at representative background locations ranged from less than 0.12 pCi/l to a maximum measured value of 1.7 pCi/l. The grand average radon level for the seven background locations was 0.50 ± 0.033 pCi/l. For comparison, a background radon level of 0.72 ± 0.42 pCi/l (average \pm two-standard error of the mean) was observed during November 1975 at five locations in the Ambrosia Lake area of active uranium mining and milling (Eadie, et al., 1976).

The remaining four sampling locations showed ambient radon levels in excess of this typical background level (i.e., greater than 0.50 ± 0.033 pCi/l). The Jackpile Housing Area (Table A-9) is obviously in immediate proximity to the ore body and mining activities. The two sampling stations near the railroad (Tables A-10 and A-11) showed elevated radon levels possibly due to ore spillage or the use of mine overburden material along the right-of-way. Ambient radon levels measured at the IHS-Laguna Health Center (Table A-3) are only slightly elevated compared to the background locations and probably reflect the natural variability of radon emanation from uranium bearing minerals in the local geologic structure. For comparison purposes, current federal and state exposure limits for radon-222 concentrations are shown in Table 4.

INTERLABORATORY COMPARISONS

During this study, radon analyses were completed at both the Eberline Instrument Corporation and at the U.S. EPA, Environmental Monitoring and Support Laboratory in Las Vegas, Nevada (EMSL) on 18 different replicate samples (i.e., two separate sample aliquots drawn from the same Tedlar bag), as shown in Table 5.

The EMSL technique used a radon concentration apparatus (Johns, 1975) capable of analyzing a 5-liter sample and counting on a 2-inch diameter photomultiplier tube using the standard 125-ml Lucas cell. The Eberline method employed the 0.51-liter scintillation flask as described above, with no sample concentration. Therefore, considering only the counting error terms, 10 of the 18 replicates were within the two-sigma counting error terms of each other (a 56 percent agreement). On the whole, the Eberline results ranged up to a factor of 6 times the replicate results from the EMSL. For radon concentrations less than 0.11 pCi/l, the Eberline analyses averaged about four times the value as reported by EMSL. For radon levels greater than 0.11 pCi/l, the Eberline results were less than twice the EMSL determinations. Obviously, the lower sensitivity of the EMSL radon determinations (due to the larger sample size) emphasizes the limit of the scintillation flasks for completing analysis at typical background radon concentrations without enrichment of the sample. Since only six out of the total 99 samples of this study were at a radon concentration less than 0.12 pCi/l, the reported radon values from Eberline are probably within a factor of two of the "real" level and therefore, the Eberline results reported here have been considered as valid results.

INDOOR RADON PROGENY LEVELS

SAMPLING SYSTEM AND ANALYTICAL METHODS

The indoor radon progeny levels were measured using a Type II, TLD-Radon Progeny Integrating Sampling Unit (RPISU) (Schiager, 1971). This sampling unit uses thermoluminescent dosimeter disks (TLD) to absorb the alpha particle emissions from the radon progeny collected on a membrane filter through which the sampled air has passed.

The measurement of stored energy in the exposed TLD disk was obtained with a Harshaw Model 2000-TLD reader. The reader gave a readout (in nanocoulombs) which was converted to a working level (WL) value by utilizing a working level-liter per nanocoulomb ($WL-1/nC$) conversion factor which was obtained through calibration tests in known radon progeny atmospheres. All WL determinations were completed at the Office of Radiation Programs-Las Vegas Facility (ORP-LVF).

RESULTS AND DISCUSSION

Three locations were selected for conducting the indoor radon progeny level determinations - the Laguna Tribal Building (#2), the Paguate Community Center, and the Jackpile Housing (#16 House). This study ran for one year from December 1975 to December 1976 and all sample results (i.e., ambient values uncorrected for background level) are shown in Tables 6 to 8. Samples indicated as "NV" are not valid due to some type of operational error associated with the sample collection. For example, misreading time clock resulted in negative sample collection time, or having a non-determinable off flowrate could not permit the correct sampled volume determination. Hence, such NV samples were ignored and were not included in the averaging process.

The arithmetic average ambient working level value of 0.0049 ± 0.00045 WL (ranging from 0.0017 to 0.0094 WL) obtained at the Laguna Tribal Building (#2) (Table 6) appears to be a representative background level. For a similar

study conducted in the Grants area of active uranium mining and milling operations, a mean "background" working level of 0.0069 WL was obtained during November 1975 (Eadie et al., 1976). Therefore, for the purposes of this study, the value of 0.0049 ± 0.00045 WL is considered to be the background working level in the vicinity of the Jackpile Mine.

The arithmetic average ambient working level obtained at the Jackpile Housing was 0.015 ± 0.0025 WL (ranging from 0.0023 to 0.038 WL) (Table 7). Subtraction of the average representative background value of 0.0049 WL yields an average net value of 0.010 WL for the Jackpile Housing.

The arithmetic average ambient working level obtained at the Paguate Community Center was 0.035 ± 0.0038 WL (ranging from 0.0082 to 0.073 WL) (Table 8). Subtraction of the average representative background value of 0.0049 WL yields an average net value of 0.030 WL for the Paguate Community Center. These relatively high working levels appear to be caused by the build-up of radon progeny due to the exhalation from the natural radium content of the dirt floor and adobe block walls. Samples of the dirt floor material averaged 0.90 ± 0.18 pCi of radium-226 per gram. Soil samples outside this structure also had a similar radium content of 1.1 ± 0.19 pCi/g. Unfortunately, a sample of the adobe block could not be obtained for analysis of radium content. Also, high equilibrium concentrations of radon progeny would be expected for this structure since it was seldom occupied and had rather poor natural ventilation. For the period 6/8 to 6/30/76, the average ambient outdoor radon concentration measured at the Paguate Community Building was 0.42 pCi/l (Table A-8). At 100% equilibrium with its daughters, and assuming that the indoor level was equal to and due solely to this measured outdoor radon level, a maximum working level of only 0.0042 WL would be expected. However, for essentially the same time period (i.e., 6/4 to 7/2/76), the measured indoor working level averaged 0.033 WL (Table 8) -- over seven times greater than could be explained on the basis of the outdoor radon concentration. Therefore, since the measured indoor working levels cannot be substantiated by the observed outdoor radon levels, the build-up of radon progeny levels must be attributable to the radium content of the dirt floor and adobe block wall construction versus radon releases from nearby mining activities.

Figure 2 shows a plot of the ambient working level values obtained for these three sampling locations. This graphic display provides some evidence of the seasonal variation in indoor radon progeny levels, with the winter months exhibiting higher working levels than the summer months. This feature was probably the result of higher radon progeny equilibrium concentrations due to poor ventilation rates in the winter when the doors and windows were usually closed.

RADON AND PROGENY EQUILIBRIUM RATIOS

Assuming that the indoor radon concentration would be equal to the measured ambient outdoor level, the percent equilibrium of radon and its progeny may be calculated. These results are shown in Table 9. The 96 percent equilibrium calculated for results at Old Laguna (#1) indicates a rather high value but is not too unreasonable since the structure was seldom used and was unoccupied during most of the study period. The other two equilibrium values exceed 100 percent and signify that it is erroneous to assume that the indoor radon levels are equal to the measured outdoor concentrations. It should be noted that the radon levels were obtained during June; whereas, the working level determinations were averaged for an entire year. Therefore, the yearly average indoor radon levels are probably in excess of the reported 1.1 and 0.42 pCi/l for these two locations. These high equilibrium values provide further incentive to conduct monitoring over longer time periods in order to determine the seasonal variability of ambient radon concentrations and its effect on indoor radon progeny levels.

TABLE 9. RADON AND PROGENY EQUILIBRIUM INDICATIONS

Location	Average Ambient Outdoor Radon During June 1976 (pCi/l)	Yearly (1976) Average Indoor Radon Progeny (Working Level)	Percent Equilibrium*
Laguna (#2)	0.51 ± 0.29	0.0049	96
Jackpile Housing	1.1 ± 0.34	0.015	136
Paguate	0.42 ± 0.14	0.035	833

*Percent equilibrium equals the working level value divided by the ambient radon concentration divided by 100 pCi/l; since, one working level is equivalent to 100% equilibrium of 100 pCi/l radon and its progeny.

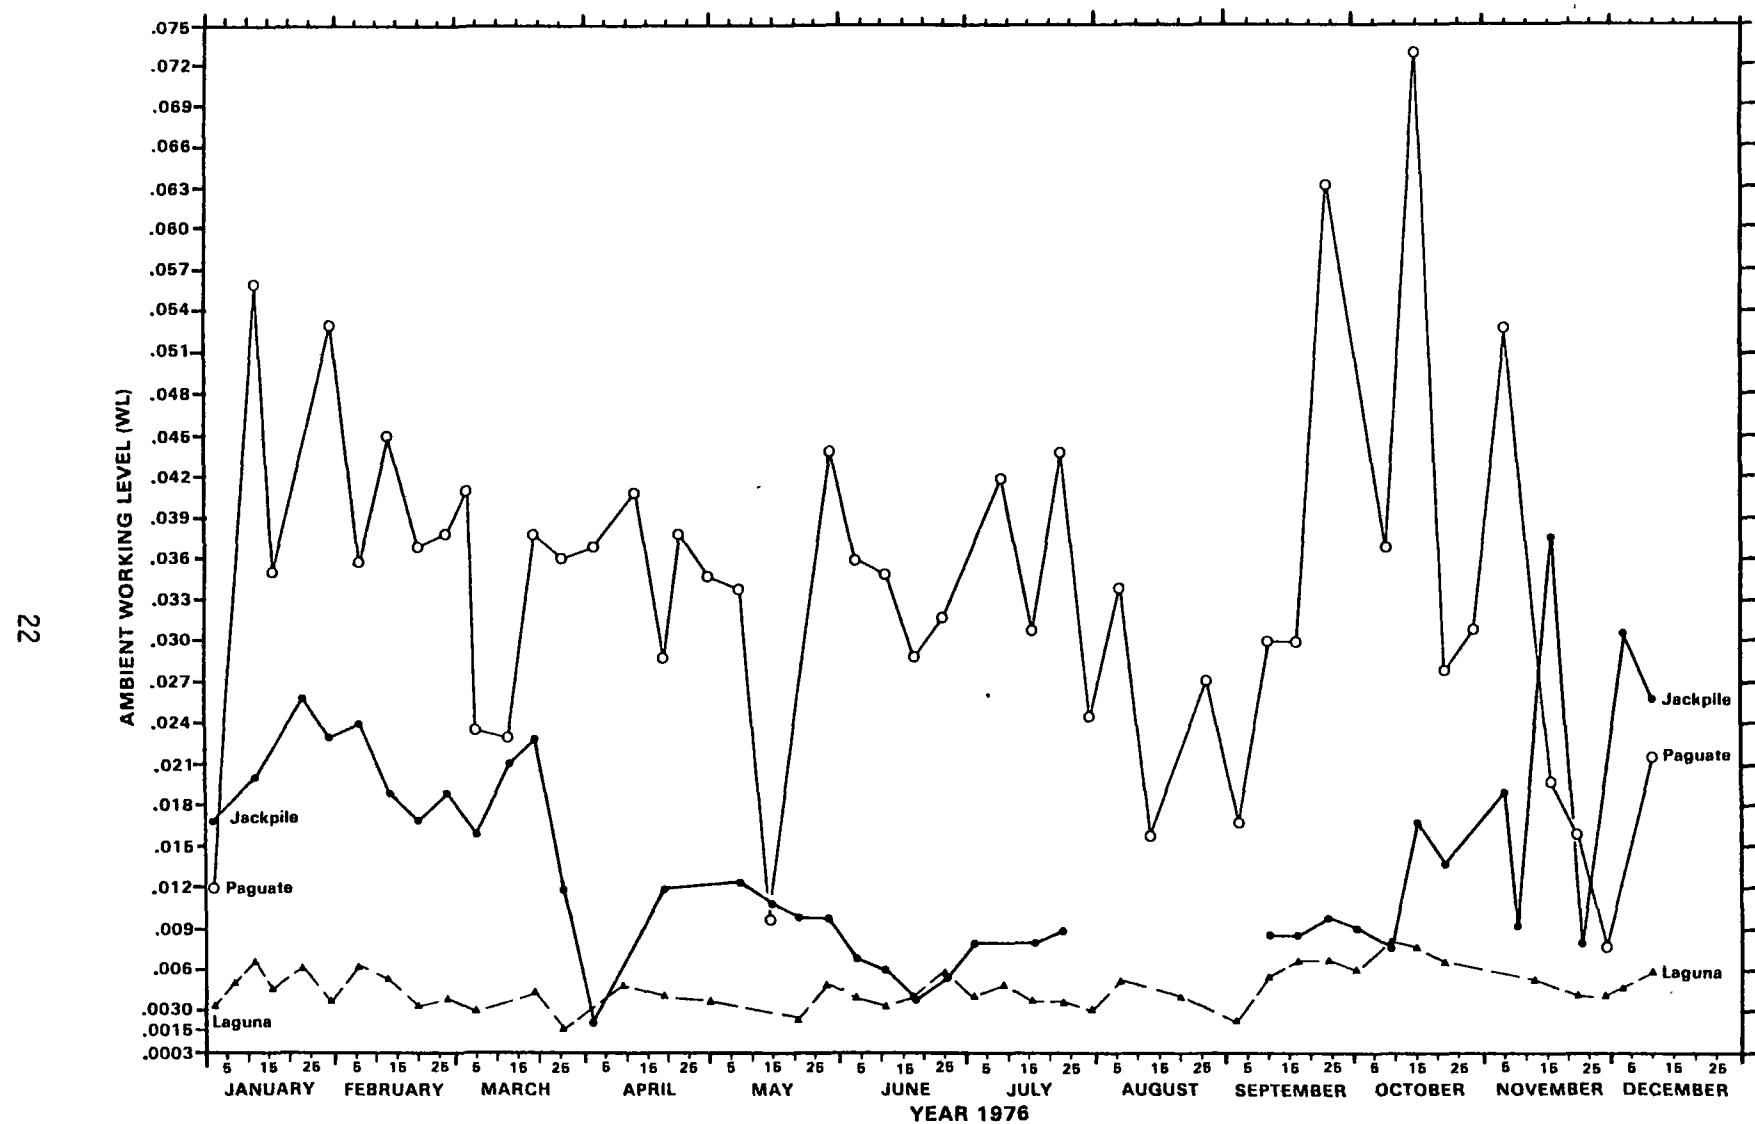

Figure 2. Ambient indoor radon progeny working levels during 1976

REGULATIONS AND GUIDELINES

Current Nuclear Regulatory Commission regulations (January, 1976) limit radon progeny levels to 0.03 working levels (above natural background) for continuous exposure in unrestricted areas (Table 4). Another guideline for continuous exposure to indoor radon progeny concentrations was established by the U.S. Surgeon General in 1970. These guides were promulgated as a result of the health hazard evaluation of the use of uranium mill tailings material for construction purposes. These guides provide remedial action recommendations for three ranges of working level values above natural background. In summary, for locations with WL values less than 0.01 WL, no remedial action is recommended. For sites exceeding 0.05 WL, remedial action to reduce WL exposure is indicated. For the range 0.01 to 0.05 WL, the need for any remedial action may be suggested after due consideration of all exposure routes and cost estimates of remedial action alternatives. These Surgeon General Guidelines have effectively been applied to the Grand Junction, Colorado remedial action program for structures incorporating tailings material. The natural background WL value for the Grand Junction area was determined to be 0.004 WL (Joint Committee on Atomic Energy, 1971).

LOG-PROBABILITY DISTRIBUTION OF INDOOR RADON PROGENY LEVELS

The following discussion is offered as a simple approach for comparison of data collected at the various sampling locations. Although it is recognized that the data may represent more than one distribution superimposed upon another, the plotted lines represent the best least squares fit of all data points for an exponential function (Brownlee, 1965). Figures 3, 4 and 5 are log-normal probability plots of the observed ambient indoor radon progeny levels, expressed as working levels (WL), for Laguna, Jackpile Housing and Paguate. The geometric mean (\bar{X}_g) is given by the fiftieth cumulative percent intercept. The geometric standard deviation (S_g) is indicated by the slope of the line and is usually calculated by dividing the working level value at the 84 percentile by the working level value at the 50 percentile.

The goodness of fit of the data points on these log-probability plots, as illustrated by Figures 3, 4 and 5, provides an indication that the measured indoor working levels can generally be described by the log-normal distribution. Also shown on the plots are the respective arithmetic averages (\bar{X}), taken from Tables 6, 7, and 8. Obviously, the best estimate of the annual average would be a time or volume weighted arithmetic average of samples collected on a continuous basis over the annual cycle; however, the collection of such samples is often difficult to achieve due to equipment or operator shortcomings. However, the arithmetic average can be estimated from the parameters of the log-normal distribution by the equation:

$$\bar{X}' = \bar{X}_g e^{(\ln S_g)^2/2}$$

For example, from Figure 3, using $\bar{X}_g = 0.0051$ WL and $S_g = 1.35$ (all data), the estimated arithmetic average (\bar{X}') was calculated to be 0.0051 WL -- essentially identical to the geometric mean value. Similarly, from the log-normal parameters obtained from Figures 4 and 5, the estimated arithmetic averages (\bar{X}') were calculated to be 0.019 WL and 0.040 WL, respectively. Therefore, the highest relative error between the arithmetic average (\bar{X}) versus the estimated average obtained from the log-normal parameters (\bar{X}') was 27 percent for the data from Jackpile Housing (Figure 4).

In order to test the adequacy of conducting less frequent sampling to estimate the annual average indoor radon progeny level, data obtained during this study for the first week of each even numbered month, and also for each odd numbered month, was also plotted for each sampling location. (As shown in Figure 2, there appears to be some seasonal variability of indoor working levels, hence the proposed sampling scheme covering every-other month over a one year period should eliminate this possible sampling bias.) On the plots, the geometric mean and standard deviations are shown with sub-scripts "ge" for the even number months and similarly, "go" for the odd months. As an example, from Figure 3, the arithmetic average (\bar{X}) working level at Laguna was 0.0049 WL. The geometric mean (\bar{X}_g) obtained from the best-fit curve of all data was 0.0051 WL. The geometric mean for the first week data of even numbered months (\bar{X}_{ge}) was 0.0054 WL, and similarly, \bar{X}_{go} was 0.0047 WL. Estimates of the annual average based on the log-normal parameters for the even and odd month sampling scheme resulted in relative errors of 16 and 1.5 percent for the Laguna data (Figure 3).

Similar statistical analysis of the data obtained at Jackpile Housing and Paguate indicate a relative error of less than 24 percent for conducting one week sampling for every-other month. Based on this limited data, it would appear that to be cost effective and to maximize equipment and manpower utilization, completion of a one week sampling period using the RPISU sampler for every other month over at least a year's duration would provide sufficient data to plot a log-probability distribution from which the annual average indoor radon progeny level could be reasonably estimated from the log-normal parameters.

AIRBORNE PARTICULATE SAMPLING

SYSTEM DESCRIPTION

Air particulate sampling was conducted using a heavy-duty air sampler*. This sampler has a carbon-vane pump with a 10.5 cubic feet per minute (CFM) free flow capacity. The pump was driven through a V-belt system by a 110-volt, 3/4-hp motor equipped with thermal overload protection. Each unit had a built-in vacuum gauge, and was calibrated to provide a calibration curve of air flow rate versus pressure drop. A running time meter, with readout to tenths of an hour, measured the total sampling time and could be reset to zero for each new sampling period. The air volume collected was determined from the calibration curve by averaging the "on" and "off" air flow rates and multiplying this average by the total time of sample collection. A quick change filter holder was mounted at one meter above the ground surface and was secured such that the open face of the (four-inch diameter) filter was toward the ground. For this study, Microsorban filters were used.

GROSS VERSUS NET RESULTS

Eadie and Bernhardt (1976) have reported that radiochemical analyses of blank (i.e., unused) four-inch diameter Microsorban filters indicate some low-level content of naturally-occurring radioactivity. Such activity may be due to the composition of the filter media itself, or due to contaminants in reagents, glassware, or other analytical equipment. The analytical sensitivity of the radiochemical techniques may also mask the identification of the true source of such low levels of radioactivity.

Table 10 presents data on the radioactivity content of blank Microsorban filters which were used for this study. In order to account for this radioactivity content associated with blank filter analyses, the appropriate blank filter activity (Table 10) has been subtracted from the measured gross analytical

result to obtain an "adjusted gross" result. Only blank radioactivity contents for isotopic uranium and radium-226 were subtracted from the gross analytical result to obtain the reported values. The reported isotopic thorium values are gross analytical results. Although air samples were also analyzed for polonium-210, lead-210 and radium-228 contents, subsequent evaluation of the analytical procedures uncovered technical problems and hence, these particular analytical results have not been reported.

RESULTS AND DISCUSSION

Air sampling was conducted at five locations - - Jackpile Housing, Paguate, Bibo, Mesita, and Old Laguna. The radioactivity concentrations of the naturally-occurring radionuclides are usually expressed as picocuries per cubic meter of ambient air (pCi/m^3). Dust loading of the air filter samples was also determined and the specific activity of the dust, expressed as pCi/g , is also given. The solubility of airborne particulate matter was not determined for this study.

The composited monthly ambient air sampling results (in pCi/m^3) are presented in Tables B-1 to B-5. These data reporting considerations are discussed in Eadie and Bernhardt (1976). Tables C-1 to C-5 contain the summary results of dust loading determinations (in pCi/g) for these same samples. Appendices D and E contain the individual adjusted ambient air sampling results in units of pCi/m^3 and pCi/g , respectively. An appropriate "normal background" value has not been subtracted from any of these reported results. Tables 11 and 12 summarize the annual average ambient air sampling radiological results in units of pCi/m^3 and pCi/g respectively, for the five locations of this study. Also shown in Table 11 are background concentrations as reported in NCRP, 1975. Comparison of these values to results from this study indicates that the airborne concentrations measured at Old Laguna appear to be at typical background levels. (This result is consistent with the observed background levels of radon and progeny which were discussed above.)

Figures 6, 7 and 8 also show the monthly average airborne concentrations (in pCi/m^3) of radium-226, total uranium and thorium-230 measured at these sampling locations for the year 1976. Comparison of these graphs indicates a seasonal variability specific to each location but having no common cycle for

all the locations. For example, at Mesita (Table B-4), the radium-226 airborne concentration ranged up to a factor of 17 between the minimum measured in August and the maximum measured in July. Similar comparison of results obtained at Bibo (Table B-3) result in only a factor of 6 between the minimum value measured in January and the maximum in June. Such incongruities with respect to month of maximum or minimum airborne concentrations may be a reflection of the level of industrial activity in that particular area or perhaps, a change in meteorological conditions. Such a situation provides further support for the need for long-term sampling schemes per specific site to evaluate the impact of the seasonal variability of airborne radioactivity.

LOG-PROBABILITY DISTRIBUTION OF AMBIENT AIRBORNE PARTICULATE RADIOACTIVITY

Log-normal probability plots of the composited monthly ambient radioactivity concentrations for the five sites for radium-226, total uranium and thorium-230 are shown in Figures 9, 10 and 11, respectively. The plotted lines represent the best least squares fit of all data points for an exponential function (Brownlee, 1965). The visual inspection of these log-probability plots provides an indication that the measured ambient airborne radioactivity concentrations can generally be described by the log-normal distribution. Table 13 shows the comparison between the arithmetic average (\bar{X}_a), the volume weighted arithmetic average (\bar{X}_w), the geometric mean (\bar{X}_g), and the estimated average based on the log-normal parameters (\bar{X}') for each sampling site. Except for the total uranium results at Mesita, \bar{X}_g was always less than \bar{X}_w (Table 13). This feature of the geometric mean is probably due to the equal weighting of all data points when obtaining the log-probability plots; whereas, the volume weighted arithmetic average takes into account the sample size and gives more "weight" to the larger samples. Also, the larger samples result in more accurate analytical determinations since there is more radioactivity to measure and consequently, better counting statistics are obtained as compared to analytical results from smaller samples. Obviously, simple arithmetic averaging (i.e., without weighting factors) also does not consider sample size and provides equal weight for each sample. It would therefore seem appropriate to choose the volume weighted arithmetic average as the best estimate of the annual average airborne radioactivity concentration. Considering the volume weighted arithmetic average (\bar{X}_w) as the best estimate of the annual average airborne radioactivity concentration, the highest relative error associated with estimating the average based on the log-normal parameters was 89 percent for the thorium-230 results at Mesita. Except for the total uranium data obtained at Mesita, the relative error between the \bar{X}_w versus the \bar{X}' was much less than 15 percent - - providing further support that it is reasonable to assume a log-normal distribution for the airborne particulate radioactivity and that annual averages may be reasonably estimated based on the log-normal parameters.

DOSE ESTIMATES

Listed in Table 14 are the dose conversion factors for each radionuclide measured in this study. (The doses due to polonium-210 and lead-210 have not been estimated since these radionuclides were not evaluated for this study.) This factor represents the average annual dose equivalent in rems for each year of chronic inhalation at a concentration of 1 pCi/m³. Dose estimates have been maximized by assuming that the indoor concentration of radioactive materials would be the same as the levels measured outdoors during this study. The highest total dose of 38 millirem was calculated for an individual exposed to the annual average ambient radionuclide concentrations measured outdoors at the Jackpile Housing (assuming continuous exposure for the entire year at the volume weighted arithmetic average value reported in Table B-1). Similarly, a total dose of 2.7 millirem was calculated for an individual exposed to the annual average ambient radionuclide concentrations measured outdoors at Old Laguna - - the location having the lowest measured ambient airborne concentrations of this study. Therefore, considering Old Laguna as representative of "background" conditions, the additional dose to an individual (above background) at Jackpile Housing would be about 35 millirem for each year of exposure to the airborne radionuclide concentrations measured during this study. For comparison purposes the dose estimates for typical background concentrations of naturally occurring radioactive materials as reported for New York City and Argonne National Laboratory (NCRP, 1975) are also tabulated in Table 14.

TABLE 14. AVERAGE ANNUAL LUNG DOSE (MREM/YEAR) FOR INSOLUBLE RADIONUCLIDES

Isotope	Dose Conversion Factor*	Jackpile Housing	Paguate	Bibo	Mesita	Old Laguna	New York City (NCRP, 1975)	Argonne National Laboratory (NCRP, 1975)
U-234	3.7	10	4.4	1.4	1.1	0.93	0.93	0.44

Total Dose (mrem/year)		38	17	4.5	4.2	2.7	1.4	1.1

* Rem per year for continuous inhalation of 1 pCi/m³ for particles of 1.0 μm AMAD; using a quality factor for alpha of 10, and a pulmonary lung mass of 480 grams (U.S. EPA, 1973; Mills, 1976; Sullivan, 1977)

+ It has been assumed that radon-222 and its progeny escape from the aerosol particle and that the only dose is due to radium-226

RADIOACTIVITY IN FOOD

During the course of this study, some concern was expressed about the possible ingestion of radioactive materials due to their uptake by food grown in the local area. Only samples of cucumbers and onions were obtained and the results of radiochemical analyses of these food are shown in Table 15. Unfortunately, samples of meat from animals which grazed on areas close to the mining activities were not available.

Previously reported analyses of vegetables indicated a radium-226 content of less than 0.002 pCi/g (Hallden et al., 1963). Welford and Baird (1967) reported a total uranium content for vegetables of roughly 0.00053 pCi/g. The radioactive content of the cucumbers from this study are essentially comparable to these reported "typical background" values with the exception of radium-226, the results for the onions are several orders of magnitude greater than the cucumber results. The fairly high radium-226 content of the cucumbers or the relatively high thorium-232 content of the onions cannot be resolved without additional sampling and further analyses. In any event, the results reported here for cucumbers and onions may be indicative of increased plant uptake from elevated radioactivity in the soil and/or plant foliage adsorption of airborne radioactive materials. Such a possibly significant exposure pathway should not be ignored in future studies of the radiological impact of uranium mining and milling activities.

15. SUPPLEMENTARY NOTES		
16. ABSTRACT This report discusses the results of several radiological surveys conducted in the vicinity of the Jackpile Open Pit Uranium Mine in New Mexico. During June 1976, ambient radon-222 concentrations were measured at eleven locations, seven of which appear to have been at representative background radon levels - averaging 0.50 ± 0.033 pCi/l. The other four locations had average radon levels in excess of this typical background level; however, the highest measured radon concentration was 2.7 pCi/l. The arithmetic average ambient radon progeny working level obtained indoors at the Laguna Tribal Building appeared to be at a representative background level of 0.0049 ± 0.00045 WL. The arithmetic average ambient working levels obtained at the Paguate Community Center and the Jackpile Housing were 0.035 ± 0.0038 and 0.015 ± 0.0025 WL, respectively. Ambient airborne particulate radioactivity concentrations measured outdoors at Old Laguna appear to be at typical background levels; however, other locations exhibited higher annual average concentrations for the naturally-occurring radionuclides.
